Resonances and summation of divergent series

G. Gallavotti

email: giovanni.gallavotti@roma1.infn.it

Abstract: Resonances in classical mechanics lead to divergent formal series requiring multiscale analysis, i.e. renormalization group methods, to be summed.

1. Resonances

The simplest situations arise perturbing a system of \( \ell \) points \( \alpha = (\alpha_1, \ldots, \alpha_\ell) \) on a circle by a potential \( \varepsilon f(\alpha) = \varepsilon \sum_{\mu \in Z^\ell} f_\mu e^{i\mu \cdot \alpha} \), with \( f_\mu \equiv 0 \) if \( |\mu| > N \), see Fig.1. The unperturbed ordered motions give way, in general, to chaotic motions which develop amidst a rather dense net of motions which are still ordered.

![Diagram of phase space in terms of \( \ell \) rotors: \( \alpha = (\alpha_1, \ldots, \alpha_\ell) \in \mathbb{T}^\ell \).](image)

Chaotic motions “take the place” near the trajectories of unperturbed resonant motions: an unperturbed resonant motion is a motion \( \alpha \rightarrow \alpha + \omega t \) with \( \omega_0 \cdot \mu = 0 \) for some non-zero \( \mu \in \mathbb{Z}^\ell \). Without real loss of generality suppose that \( \omega_0 = (\omega, 0) \) with \( \omega \in \mathbb{Z}^r \), \( r < \ell \) and suppose that \( \omega \in \mathbb{R}^r \) are independent in the sense

\[
|\omega \cdot \nu| > \frac{1}{C|\nu|^\tau}, \quad \forall \quad 0 \neq \nu \in \mathbb{Z}^r
\]

for some \( C, \tau > 0 \) (\( \tau \geq r - 1 \), necessarily). Therefore this is a motion in which \( \alpha = (\gamma, \beta) \) moves as \( \alpha \rightarrow (\gamma + \omega t, \beta) \). There are many such motions because \( \beta \in \mathbb{T}^s \) (\( s = \ell - r \)) is arbitrary: they form a \( s \)-dimensional family of invariant tori of dimension \( r \). The angles \( \gamma \in \mathbb{T}^r \) are called fast angles while the angles \( \beta \in \mathbb{T}^s \) are called slow angles. However the chaotic motions do not completely destroy the resonant motions and some of them remain and one should think that the chaotic motions really develop “around” the few resonant motions that remain.

This explains why the theory of the surviving resonant motions is interesting: a deeper reason is that in presence of (small) friction the chaotic motions dissipate more energy and motions concentrate around the resonant motions: therefore the resonant motions are the places where to look to find the eventual behavior of random initial data (e.g. in the planetary system one finds many resonances even though the resonances fill a very small part of phase space, actually of 0 volume).

A resonant motion in presence of a perturbation with potential \( \varepsilon f \), “of strength \( \varepsilon \)”, is defined as a motion that can be represented in the form

\[
\alpha(t) \equiv (\gamma(t), \beta(t)) = (\psi + \omega t + g(\psi + \omega t), \beta_0 + k(\psi + \omega t))
\]

where \( \beta_0 \) is some point in \( \mathbb{R}^s \) and \( h(\psi) \equiv (g(\psi), k(\psi)) \) is a function of \( \varepsilon \) which should tend to 0 as \( \varepsilon \rightarrow 0 \) for some \( \beta_0 \) (hence \( \beta_0 \) identifies the surviving torus). Thus to look for resonant motions with frequencies \( (\omega, 0) \) means looking for functions \( h(\psi) = (g(\psi), k(\psi)) \) periodic and smooth on \( \mathbb{T}^r \) and for \( \beta_0 \in \mathbb{R}^s \) such that \( t \rightarrow \alpha(t) = (\psi + \omega t, \beta_0) + h(\psi + \omega t) \) solves the equations of motion \( \dot{\alpha} = -\varepsilon \partial_\alpha f(\alpha) \), or

\[
(\omega \cdot \partial_\psi)^2 h(\psi) = -\varepsilon \partial_\alpha f(\psi + g(\psi), \beta_0 + k(\psi))
\]

It should be clear that the value of \( \beta_0 \) has to be very special: namely such that the \( s \) points standing in \( \beta_0 \) feel a 0 average force at least in a first approximation (i.e. to lowest order in \( \varepsilon \)). This means that \( \beta_0 \) has to be a stationarity point for the average of the force \( \partial_\alpha f(\gamma, \beta) \) over the fast angles \( \gamma \): i.e. \( \beta_0 \) has to satisfy

\[
\partial_\beta \overline{f}(\beta_0) = 0, \quad \text{if} \quad \overline{f}(\beta) \overset{\text{def}}{=} \int f(\gamma, \beta) \frac{d^r \gamma}{(2\pi)^r} \quad (1.4)
\]

The function \( f(\gamma, \beta) \) will be written

\[
f(\gamma, \beta) = \sum_{|\nu| < N} f_\nu(\beta) e^{i\gamma \cdot \nu}
\]

so that \( \overline{f}(\beta) \equiv f_0(\beta) \). The potential is supposed to be a trigonometric polynomial in \( \gamma \) just for simplicity of exposition: the main result holds, however, even under the weaker assumption that the potential is analytic.

The problem has a formal solution that described in the next section: the results and properties are discussed in Sect.3.

2. Diagrams for the resonant series

An algorithm to solve the (1.3) is easy to devise and is described below. Consider a (rooted) tree graph \( \vartheta \) formed by \( k \) (pairwise distinct) lines oriented towards the root, see Fig.2

![Diagram of a tree graph \( \vartheta \).](image)

The extremes of each line will be called nodes but it is convenient that the root will not be considered a node. The notation \( v < w \) will denote that a node \( v \) of a tree precedes the node \( w \) of the (same) tree in the partial
order induced on the tree by the orientation of its lines. A line will be identified with its two extremes \( v'v \), with \( v' < v \), and if \( v \) is the last node before the root (which by our convention would not be a node) we set nevertheless \( v' = r \). Various labels will be attached to the tree, see Fig.3,

(1) To each node \( v < r \) of \( \mathcal{D} \) attach a harmonic \( \nu_v \in \mathbb{Z}^r \).

(2) To line \( \lambda = v'v \) attach a current \( \nu(\lambda) = \sum_{v' \leq v} \nu_{v'} \).

(3) At the two extremes of each line \( \lambda = v'v \) attach two component labels \( j', j \),

\[
\begin{align*}
\text{Component labels around } v & \quad J_F \\
\end{align*}
\]

In this way it is possible to define the coupling constant associated with the node \( v < r \): if \( v \rightarrow J_v = (j_0, \ldots, j_p) \) are the labels at the extremes of the lines entering or exiting \( v < r \) (see Fig.3) the coupling is defined as \( \partial f_{\nu}(\beta_0) \) where \( \partial f_{\nu}(\beta_0) \) is the derivative with respect to \( \beta_j \) if \( j > r \) and it is, naturally, multiplication by \( iv_j \) if \( j \leq r \).

The labels allow us to define the value of the labeled tree graph: it is defined as proportional to the product of the couplings of each node times the product of the line propagators \( g_{j'_i, j_i} \), it the line \( \ell = v'v \) has labels \( j'_i, j_\ell \) associated with \( v', v \); precisely

\[
\text{Val}(\mathcal{D}) = \frac{\varepsilon^k}{k!} \left( \prod_v \varepsilon \partial_j f_{\nu}(\beta_0) \right) \left( \prod_{\text{lineset}} g_{j_i j'_i} \right) \quad (2.1)
\]

where, if \( M_0 \equiv \left( \begin{smallmatrix} 0 & 0 \\ \varepsilon \partial^2 f(\beta_0)^{-1} & I \end{smallmatrix} \right) \) denotes the \( \ell \times \ell \) matrix with all elements 0 except the principal \( s \times s \) matrix in the lowest corner (equal to \( \partial^2 f(\beta_0)^{-1} \)), the propagators are defined by

\[
\begin{align*}
&g_{ij} \equiv \frac{\delta_{ij}}{(\omega \cdot \nu(\ell))^2}, \quad \text{if } \nu(\ell) \neq 0 \quad \text{or} \quad \nu(\ell) = 0 \quad (2.2) \\
&g_{ij} \equiv (M_0)_{ij}, \quad \text{if } \nu(\ell) = 0
\end{align*}
\]

Trees can contain nodes with just one entering line and one exiting line (the example in Fig.2 does not contain any such node): calling trivial such nodes consider only tree graphs without trivial nodes \( v \) with \( \nu_v = 0 \) and, at the same time, with the entering line having \( 0 \) current. Then

\[
h_{j,\nu} = \sum_{\mathcal{D}} \text{Val}(\mathcal{D}) \quad (2.3)
\]

where the sum is over all labeled trees with a fixed current \( \nu \) on the root line and with a fixed label \( j \), “root label”, at the highest extreme of the root line; the \( * \) reminds us that only tree graphs without trivial nodes with \( 0 \) incoming current are considered. Note that the root label \( j \) is fixed so that the function (2.3) is a \( \ell \) components vector.

This is a formal power series in \( \varepsilon \) (the \( * \) in (2.3) implies that if \( k \) is the number of nodes \( v < r \) then the number of lines with \( 0 \) current is not too large, so that the value is always a monomial in \( \varepsilon \) of order \( \geq \frac{1}{2} k \), so the \( 0 \) current lines cannot lower too much the power of \( \varepsilon \) in Val(\( \mathcal{D} \))).

The series is formal and convergence is doubtful because the best estimate that we are able to find for the coefficient \( h_{(k)} \), sum of all contributions of degree \( k \) in \( \varepsilon \), is

\[
|h_{\nu,\nu}| \leq hB_k \varepsilon^k k! \quad (2.4)
\]

which is established by taking into account (1.1).

3. Summation results

The main result can be summarized by the following theorem, taken from [GG05] where it was not noted that the proof implied that the domain in Fig.4 below instead of having a vertical tangent at the origin could be enlarged to a domain with a horizontal cusp at the origin (unpublished).

Theorem: If \( \partial^2 f(\beta_0) < 0 \) the tree series can be rearranged to yield a convergent series representation of \( h = (g(\psi), k(\psi)) \), hence its existence, in \( D(\varepsilon) \) of the form in Fig.4.

Fig.4: \( \varepsilon \in \varepsilon \); \( \varepsilon \) dense at 0. The figure illustrates the analyticity domain \( D(\varepsilon) \) associated with a single \( \varepsilon \in \varepsilon \), represented by the dot, ("elliptic case"). The cusp at the origin is quadratic.

where \( \mathcal{E} \subset (-\varepsilon_0, 0) \) is a set with open dense complement in \((-\varepsilon_0, 0) \) 0 is a density point. The set \( \cap_{\varepsilon \in \mathcal{E}} D(\varepsilon) \) contains a domain of the form in Fig.5:

Fig.5: The domains of analyticity for \( \varepsilon < 0, \varepsilon \in \varepsilon \), contain a set of this form with quadratic cusp at the origin.

Furthermore the functions \( h \) defined in each \( D(\varepsilon) \) for \( \varepsilon \in \varepsilon \) are real on the positive axis and define a solution to (1.3), i.e. also a quasi periodic motion. All functions defined in the above domains have the formal powers series as an asymptotic series at the origin and have derivatives everywhere bounded by \( O(k^{12}) \). At the origin the bound is better: \( O(k^{22}) \).

Remark: a heuristic linear stability analysis shows that the Lyapunov coefficients of the motions are either 0 (2r
of them) or real if \( \varepsilon > 0 \) and imaginary if \( \varepsilon < 0 \) (2s of them) . This is the reason why the invariant tori, if really existent, are called hyperbolic if \( \varepsilon > 0 \) and elliptic if \( \varepsilon < 0 \). A direct proof that hyperbolic tori with analytic equations in a domain of the form in Fig.5 exist would be easier and it can be found in [GG02].

The proof is based on the remark that the extra \( k! \) arise, for instance, because of the existence of graphs which contain chains of trivial nodes, like those in Fig.6, and graphs containing lines with chains of trivial nodes can be eliminated at the price of changing the propagators. In fact insertion of a trivial node \( v \) on a line as in Fig.7

![Diagram](https://via.placeholder.com/150)

generates a change in the value of the graph that can be obtained, if \( M_0 \) is the matrix defined after (2.1), by replacing the propagator matrix as

\[
\frac{\delta_{ij}}{(\omega \cdot \nu)^2} \rightarrow \frac{1}{(\omega \cdot \nu)^2} (M_0 \frac{1}{(\omega \cdot \nu)^2} )^k_{ij} \quad (3.1)
\]

after summing over the labels \( i_0, j_0 \) relative to the node \( v \) and properly taking into account the combinatorial factors.

Hence summing on the arbitrary number of insertions one can simply imagine that in (2.3) the sum extends only over graphs containing no trivial node provided the propagator matrix of each line (with \( \nu \neq 0 \)) is replaced by

\[
\frac{1}{(\omega \cdot \nu)^2} \Rightarrow \frac{1}{(\omega \cdot \nu)^2} \sum_{k=0}^{\infty} (M_0 \frac{1}{(\omega \cdot \nu)^2})^k = \frac{1}{(\omega \cdot \nu)^2 - M_0} \quad (3.2)
\]

Of course this means that we are using the rule

\[
\sum_{k=0}^{\infty} z^k = \frac{1}{1 - z} \quad \text{for} \quad z = M_0 \frac{1}{(\omega \cdot \nu)^2} \quad (3.3)
\]

However it is easy to realize that necessarily there will be \( \nu \)'s with \( |z| > 1 \). In other words using (3.2) as propagator implies accepting a rule like \( \sum_{k=0}^{\infty} 2^k = 1 + 2 + 4 + \ldots = -1 \), infinitely many times since there are infinitely many \( \nu \)'s for which \( |z| > 1 \).

On the other hand we see that if \( M_0 \leq 0 \), i.e. if \( \beta_0 \) is a maximum point for \( f(\beta) \) as supposed here, the theory is likely to be easier for \( \varepsilon > 0 \). For \( \varepsilon < 0 \) it becomes even possible that the denominators in the r.h.s. of (3.2) vanish, so that to continue the discussion we will be forced to discard the values of \( \varepsilon \) too close to values such that \( |\omega \cdot \nu| = \pm \sqrt{-\varepsilon} \mu_j \) with \( \mu_j \) a positive eigenvalue of the matrix \( \frac{\partial^2 f}{\partial \beta^2}(\beta_0) \).

The latter problem is dwarfed by the realization that there are a lot of other “chains” that one can form by inserting on any line a subtree with node harmonics adding up to 0: it is easy to check that also such more elaborated insertions produce values which can be bounded by a power of \( k! \) too. The idea is then to eliminate all such chains by resummations similar to the ones just discussed. The reason one embarks into such a program is that the following theorem by Siegel holds:

**Theorem:** Given a tree \( \theta \) let \( N_n \) be the number of lines of “scale \( n \)”: i.e. s.t.

\[
2^{-n} < C |\omega \cdot \nu| \leq 2^{-n+1} \quad (3.4)
\]

\( n = 0, 1, \ldots \). If a graph \( \theta \) contains no pair of lines \( \ell' > \ell \) with only lower intermediate scales and with \( \nu(\ell') = \nu(\ell) \), then

\[
N_n \leq 4N 2^{-n/\tau} k \quad (3.5)
\]

**Remark:** by “intermediate” between \( \ell' > \ell \) and \( \ell \) it is meant a line \( \ell < \ell' \) and either \( > \ell \) or not comparable to \( \ell \).

It is immediate to see that the sum of the values of the graphs subject to the constraint that no line \( \ell' \) which follows a line \( \ell \) has the same current is a convergent power series: because the product of the couplings is bounded by

\[
\prod_n |\partial f/\partial \nu(\beta_0)| \leq \prod_n N_{n} |J^{r_n}| F^{k} \leq N^{2k} F^{k} \quad (3.6)
\]

the number of node harmonics is bounded by \( (2N + 1)^k \) (if \( N \) is the bound on the harmonics in the potential, see (1.5)); the number of trees is bounded by \( k^{k-1} \); and the product of the small divisors is, by (3.5),

\[
\prod_n \frac{1}{(\omega_n \cdot \nu)^2} \leq C^{2k} \prod_{n=0}^{\infty} \frac{2^{nN_n}}{n!} \leq C^{2k} \left( \prod_{n=0}^{\infty} \frac{2^{n(4N 2^{-n/\tau})}}{n!} \right)^k \quad (3.7)
\]

If \( |\varepsilon| < (N^2 C^2 (2N + 1)^4 F^2 8^N \sum_n n^{2-n/\tau})^{-1} \) convergence follows.

An example of a cluster: surrounded by a circle are the lines of a tree graph with scale \( \leq n \). The dashed lines have scale \( > n \) and one
4. Outlook

At this point the idea is to iterate and eliminate, successively, the self-energy cluster of scale $1, 2, 3, \ldots$ by recursively modifying the propagators.

The difficulty is that the matrix $M_1$ might no longer have a structure allowing us to bound the denominator in the propagator from below by $\omega \cdot \nu^2$ even if $M_0 \geq 0$. Because the 0 elements in the matrix $M_0$ (defined after (2.1)) become in general $\neq 0$ when $M_0$ is changed into $M_0 + M_1$ and the matrix may become of indefinite sign even though $M_0 \leq 0$.

The next key remark is that this does not happen: the reason is that the self energy cluster values $m_1$ have special properties which imply that cancellations occur when the sum $\sum_{\Gamma}$ is performed. The cancellations have the same origin of the well known cancellations that occur in the proof of the convergence of the KAM theorem.

After remarking that the propagators remain on all scales such that their denominators can be bounded below $\omega \cdot \nu^2$ if $M_0 < 0$ the proof is reduced to Siegel's theorem.

The case $M_0 \geq 0$ (or of undefined sign) is much harder. Already the first resummation changing the propagator from $\omega \cdot \nu^{-2}$ to $\omega \nu^{-1} M_0^{-1}$ forces to discard some intervals of $\epsilon$ (which form a dense set because the values of $\omega \cdot \nu^2$ are dense as $\nu$ varies and one has to discard all $\epsilon$ such that $\sqrt{-\epsilon} \mu_j = \pm \omega \cdot \nu$ as remarked earlier, as well as the values of $\epsilon$ too close to such values). As the scale decreases and the scale $n$ with $2^{-n} \sim \epsilon$ is reached the quantity $\omega \cdot \nu^2 - M_0 - M_1 - \ldots - M_{n-1}$ can vanish for more values of $\epsilon$ leading to further values of $\epsilon$ excluded.

The number of excluded $\epsilon$'s is countable and in spite of the fact that it is dense it can have a small measure: however it is clear that the propagators denominators will not be bounded below by $\omega \cdot \nu^2$ but rather by how close $\omega \cdot \nu^2 - M_0 - M_1 - \ldots - M_{n-1}$ is to zero. Therefore Siegel's theorem does not apply directly and one has to devise an extension of it in which the scale of the propagators is measured by the smallest eigenvalue of the matrices $\omega \cdot \nu^2 - M_0 - M_1 - \ldots - M_{n-1}$, recursively constructed, see [GG05].

In the end one finds a convergent series for $\h$ which is a formal resummation of the original series (2.3): it is formal because in obtaining it the expression $\sum_{k=0}^{\infty} z^k = (1 - z)^{-1}$ for $z \neq 1$ (but $|z| > 1$) has been used, infinitely many times. Therefore it is not obvious that the equation (2.3) is solved by the function $\h$ thus constructed. Therefore the last step is to check that inserting $\h$ into (2.3) it turns it into an identity.

The details of the complete analysis can be found in [GG05]. The cusp at the origin in Fig.4 is, however, an improvement implicit in the analysis in [GG05] later noted by the authors.

4. Outlook

The analysis is an instance in which a resummation of self-energy diagrams can be performed rigorously. There are not many such examples. The multiscale analysis is a
version of a renormalization group argument: the “flow” of the propagators is analogous to the flow of the running couplings and the analogy could be made much closer by showing that the graphs can be considered as Feynman graphs of a suitable field theory on a torus (although without loops the theory is non trivial because in the graphs vertices can merge as many lines as wished, i.e. the theory is “non polynomial”), see [Ga95],[Ga01].

An important open problem is uniqueness: are the invariant tori constructed through resummations unique? this seems to be an open problem even in the case of $s = 0$, maximal dimension, non resonant tori: which is a special case of our analysis which generates the usual KAM tori (as a trivial case, see Ch.8,9 in [GBG04]). More precisely: given $\omega$ is it true that in a small enough neighborhood of the unperturbed invariant torus there is no invariant torus with rotation vector $\omega_0 = (\omega,0)$ other than the one constructed in this analysis at least for $\varepsilon$ small enough (and, of course, such that the construction works)?

Another question is: can one reconstruct the function $Vh$ from its Taylor coefficients at the origin via a procedure like Borel summation?

A third question is: is there a single analytic function $Vh$ in the region $\cup_{\varepsilon \in \mathbb{D}} \{(\varepsilon,0)\}$, see the theorem at the beginning of Sec. 3 and Figs.4,5, which on the real axis becomes a function $h$ solution of (1.3)? The region would have the form of Fig.11.

A final question is: what happens if $\det \frac{\partial^2\mathcal{F}}{\partial \beta_0^2}(\beta_0) = 0$? In the case $s = 1$ and if the first non vanishing derivative, at $\beta_0$, is of order $k_0 + 1$ (with $k_0 > 1$) one can expect analyticity in a fractional power of $\varepsilon$ (namely $|\varepsilon|^{1/k_0}$), for $\varepsilon$ outside some set $E$ with 0 a density point.

The above seem to me interesting and relevant questions.

Acknowledgement: The above work is the conclusion of a long collaboration with Guido Gentile. I am indebted to A. Giuliani for many helpful comments.
